

A decorative L-shaped line in a light brown color, consisting of a vertical segment on the left and a horizontal segment on the top, framing the title text.

# Machine Learning Assignment

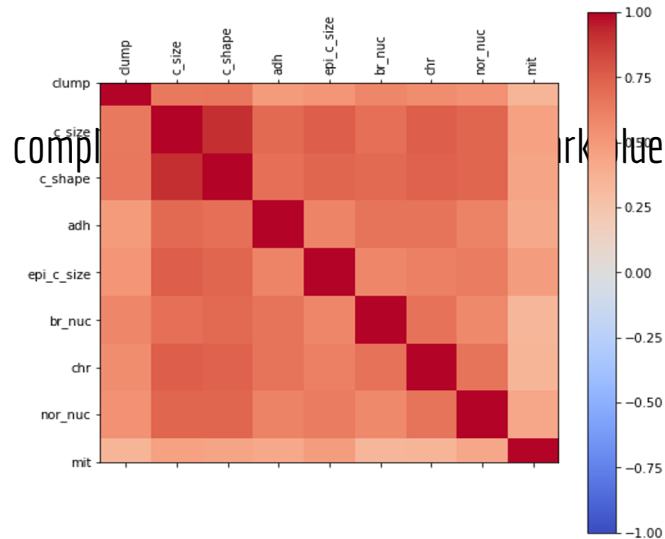

A decorative L-shaped line in a light brown color, consisting of a vertical segment on the right and a horizontal segment on the bottom, framing the author text.

K.Anjali Kamath

# Dataset-cleaning and processing

Each column in the dataset was of type 'str'. All the values were converted to 'int' datatype before cleaning. There were 16 instances in groups 1-6 that contained a single missing attribute value. The dataset was cleaned by replacing the missing values(?) in a particular column by the mean of the column.

Correlation matrix:

Here, maroon signifies

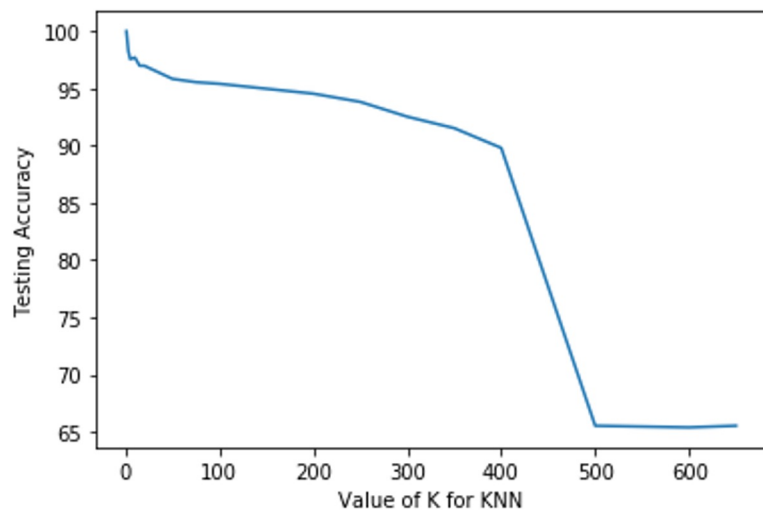

signifies no correlation between the attributes (-1.00).

# KNN

KNN or k-Nearest Neighbours is an algorithm which is used for regression and classification. It classifies data based on some similarity measure. Here, we used Euclidean distance as the basis for classifying the data points.(for k=5)

```
Confusion Matrix :  
[[450  8]  
 [ 26 212]]  
Accuracy Score : 0.9511494252873564  
Report :
```

	precision	recall	f1-score	support
2	0.95	0.98	0.96	458
4	0.96	0.89	0.93	238
accuracy			0.95	696
macro avg	0.95	0.94	0.94	696
weighted avg	0.95	0.95	0.95	696

# Weighted KNN

As the accuracy obtained for ordinary knn was very high,we assigned weights to each neighbour ,thereby increasing/decreasing that neighbours effect. The accuracy remains low initially for smaller k values then increases significantly.

Confusion Matrix :

```
[[298 158]
```

```
[ 4 236]]
```

macro avg	0.92	0.94	0.93	696
weighted avg	0.94	0.93	0.93	696

# Logistic Regression

Logistic model is used to model the probability of a certain class or event existing. Here we use it to predict the class (Benign/Malignant). Data was first normalised. Then the class for each row in the dataset was predicted using the formula given below. (i.e. We used sigmoid function). The predicted class was then rounded off to 2 decimal places and compared with the actual class and the error was calculated. Then the coefficients (b) for every column was updated based on the formula:  $b = b + (\text{error} * \text{learning\_rate} * \text{predicted\_value} * (1 - \text{predicted\_value}) * x$

The final predicted class was then compared with the actual class and accuracy was calculated.

The maximum accuracy that we could achieve was 83.33% when the learning\_rate was 0.93, and the number of epochs was 3000.

$$p = \frac{1}{1 + e^{-(b_0 + b_1x_1 + b_2x_2 + \dots + b_px_p)}}$$

# ANN

Random weights in the range [1-100] were assigned to each input. The weights were then normalized. Then the dot product/linear combination of the inputs and weights was found for each layer in the network (we used only 1 hidden layer). The outputs of one layer become the inputs of the next layer. This is how forward propagation is implemented. The activation function used is reLu (Rectified Linear Unit). The final output is then compared with the expected output and the error is calculated using the formula  $\text{error} = (\text{expected} - \text{observed})^2$ . The total error is found by summing the individual errors of each layer. In back propagation, this error is used to update weights accordingly. A learning rate is specified which is used to update the weights. At each epoch, the epoch number, learning rate and the total error is printed.
